

Calibrated Data Augmentation for Scalable Markov Chain Monte Carlo

Leo L. Duan, James E. Johndrow, David B. Dunson

February 6, 2017

Abstract: Data augmentation is a common technique for building tuning-free Markov chain Monte Carlo algorithms. Although these algorithms are very popular, autocorrelations are often high in large samples, leading to poor computational efficiency. This phenomenon has been attributed to a discrepancy between Gibbs step sizes and the rate of posterior concentration. In this article, we propose a family of calibrated data augmentation algorithms, which adjust for this discrepancy by inflating Gibbs step sizes while adjusting for bias. A Metropolis-Hastings step is included to account for the slight discrepancy between the stationary distribution of the resulting sampler and the exact posterior distribution. The approach is applicable to a broad variety of existing data augmentation algorithms, and we focus on three popular models: probit, logistic and Poisson log-linear. Theoretical support is provided and dramatic gains are shown in applications.

KEY WORDS: Bayesian probit; Bayesian logit; Big n ; Data Augmentation; Maximal Correlation; Polya-Gamma.

1 Introduction

With the deluge of data in many modern application areas, there is pressing need for scalable computational algorithms for inference from such data, including uncertainty quantification (UQ). Somewhat surprisingly, even as the volume of data increases, uncertainty often remains sizable. Examples in which this phenomenon occurs include financial fraud detection (Ngai et al., 2011), disease mapping (Wakefield, 2007) and online click-through tracking (Wang et al., 2010). Bayesian approaches provide a useful paradigm for quantifying uncertainty in inferences and predictions in these and other settings.

The standard approach to Bayesian posterior computation is Markov chain Monte Carlo (MCMC) and related sampling algorithms. Non-sampling alternatives, such as variational Bayes, tend lack general accuracy guarantees. However, it is well known that conventional MCMC algorithms often scale poorly in problem size and complexity. Due to its sequential nature, the computational cost of MCMC is the product of two factors: the evaluation cost at each sampling iteration and the total number of iterations needed to obtain

an acceptably low Monte Carlo error. The latter is related to the properties of the Markov transition kernel; we will refer to this informally as the *mixing properties* of the Markov chain.

In recent years, a substantial literature has developed focusing on decreasing computational cost per iteration (Minsker et al. (2014); Srivastava et al. (2015); Conrad et al. (2015) among others), mainly through accelerating or parallelizing the sampling procedures at each iteration. Moreover, myriad strategies for improving mixing have been described in the literature. For Metropolis-Hastings (M-H) algorithms, improving mixing is usually a matter of constructing a better proposal distribution. An important difference between M-H and Gibbs is that one has direct control over step sizes in M-H through choice of the proposal, while Gibbs step sizes are generally not tunable; on the other hand, finding a good proposal for multi-dimensional parameters in M-H is significantly more challenging compared to Gibbs sampling. Thus, improving mixing for Gibbs has historically focused on decreasing autocorrelation by changing the update rule itself, for example by parameter expansion (PX), marginalization, or slice sampling.¹

The theory literature on behavior of MCMC for large n and/or p is arguably somewhat limited. Many authors have focused on studying mixing properties by showing an ergodicity condition, such as geometric ergodicity (Roberts et al., 2004; Meyn and Tweedie, 2012). This generally yields bounds on the convergence rate and spectral gap of the Markov chain, but Rajaratnam and Sparks (2015) observe that in many cases, these bounds converge to zero exponentially fast in p or n , so that no meaningful guarantee of performance for large problem sizes is provided by most existing bounds. In the probability literature, a series of papers have developed an analogue of Harris’ theorem and ergodic theory for infinite-dimensional state spaces (Hairer et al., 2011). Recent work verifies the existence of MCMC algorithms for computation in differential equation models with dimension-independent spectral gap (Hairer et al., 2014). In this example, the algorithm under consideration is an M-H algorithm, and it is clear that the proposal must be tuned very carefully to achieve dimension independence. Other work has studied the properties of the limiting differential equation that describes infinite-dimensional dynamics of MCMC.

A recent paper (Johndrow et al. (2016)) studies popular data augmentation algorithms for posterior computation in probit (Albert and Chib, 1993) and logistic (Polson et al., 2013) models, showing that the algorithms fail to mix in large sample sizes when the data are imbalanced. An important insight is that the performance can be largely explained by a discrepancy between the rate at which Gibbs step sizes and the width of the high-probability region of the posterior converge to zero as the sample size increases. Thus, since Gibbs step sizes are generally not tunable, slow mixing is likely to occur as the sample size grows unless the order of the step size happens to match the order of the posterior width. This implies that if a way to directly control the step sizes of the Gibbs sampler could be devised, it would be possible to make the mixing

¹Although strictly speaking, slice sampling is just an alternative approach to sampling from a full conditional distribution, in practice, it is often an alternative to data augmentation, so that using a slice sampling strategy results in the removal of a data augmentation step from an alternative Gibbs sampler.

properties of the sampler insensitive to sample size by scaling the step sizes appropriately. This is similar to the conclusion of Hairer et al. (2014), except in this case, we have growing n instead of growing p .

In this article, we propose a method for tuning Gibbs step sizes by introducing auxiliary parameters that change the variance of full conditional distributions for one or more parameters. Although we focus on data augmentation algorithms for logit, probit, and Poisson log-linear models, in principle the strategy can be applied more generally to align Gibbs step sizes with the size of the space being explored. As these “calibrated” data augmentation algorithms alter the invariant measure, one can use the Gibbs step as a highly efficient M-H proposal, thereby recovering the correct invariant, or view the resulting algorithm as a perturbation of the original Markov chain. In this article, we focus on the former strategy, providing theoretical support and showing very substantial practical gains in computational efficiency attributed to our calibration approach.

2 Calibrated Data Augmentation

Data augmentation Gibbs samplers alternate between sampling latent data z from their conditional posterior distribution given model parameters θ and observed data y , and sampling parameters θ given z and y ; either of these steps can be further broken down into a series of full conditional sampling steps but we focus for simplicity on algorithms of the form:

$$\begin{aligned} z \mid \theta, y &\sim \pi(z; \theta, y) \\ \theta \mid z, y &\sim f(\theta; z, y), \end{aligned} \tag{1}$$

where f belongs to a location-scale family, such as the Gaussian. Popular data augmentation algorithms are designed so that both of these sampling steps can be conducted easily and efficiently; e.g., sampling the latent data for each subject independently and then drawing θ simultaneously (or at least in blocks) from a multivariate Gaussian or other standard distribution. This effectively avoids the need for tuning, which is a major issue for Metropolis-Hastings algorithms, particularly when θ is high-dimensional. Data augmentation algorithms are particularly common for generalized linear models (GLMs), with $\mathbb{E}(y_i \mid x_i, \theta) = g^{-1}(x_i \theta)$ and a conditionally Gaussian prior distribution chosen for θ . We focus in particular on Poisson log-linear, binomial logistic, and binomial probit as motivating examples.

We provide brief motivation for our approach, with further theoretical development in section XXX. Consider a Markov kernel $K((\theta, z); \cdot)$ with invariant measure Π and update rule of the form (1), and a Markov chain (θ_t, z_t) on a state space $\Theta \times \mathcal{Z}$ evolving according to K . We will abuse notation in writing $\Pi(d\theta) = \int_{z \in \mathcal{Z}} \Pi(d\theta, dz)$. The lag-1 autocorrelation for a function $g : \Theta \rightarrow \mathbb{R}$ at stationarity can be expressed

as the Bayesian fraction of missing information [CITES]

$$\gamma_g = 1 - \frac{\mathbb{E}[\text{var}(g(\theta) \mid z)]}{\text{var}(g(\theta))}, \quad (2)$$

where the integrals in the numerator are with respect to $\Pi(d\theta, dz)$ and in the denominator with respect to $\Pi(d\theta)$. Let

$$L_2(\Pi) = \left\{ g : \Theta \rightarrow \mathbb{R}, \int_{\theta \in \Theta} \{g(\theta)\}^2 \Pi(d\theta) < \infty \right\}$$

be the set of real-valued, Π square-integrable functions. The *maximal autocorrelation*

$$\gamma = \sup_{g \in L^2(\Pi)} \gamma_g = 1 - \inf_{g \in L^2(\Pi)} \frac{\mathbb{E}[\text{var}(g(\theta) \mid z)]}{\text{var}(g(\theta))}$$

is equal to the geometric convergence rate of the data augmentation Gibbs sampler [CITES]. For $g(\theta) = \theta_j$ a coordinate projection, the numerator of the last term of (2) is, informally, the average squared step size for augmentation algorithm at stationarity in direction j , while the denominator is the squared width of the bulk of the posterior in direction j . Consequently, γ will be close to 1 whenever the average step size at stationarity is small relative to the width of the bulk of the posterior.

The purpose of CDA is to introduce working parameters that allow us to control the step size relative to the posterior width – roughly speaking, the ratio in (2) – with greater flexibility than reparametrization or parameter expansion. The flexibility gains are achieved by allowing the invariant measure to change as a result of the introduced parameters. The working parameters, which we denote (r, b) , correspond to a collection of reparametrizations, each of which defines a proper (but distinct) likelihood $L_{r,b}(\theta; y)$, and for which there exists a Gibbs update rule of the form (1). The reparametrization also has the property that $L_{1,0}(\theta; y) = L(\theta; y)$, the original likelihood. The resulting Gibbs sampler, which we refer to as CDA Gibbs, has θ -marginal invariant measure $\Pi_{r,b}(\theta; y) \propto L_{r,b}(\theta; y) \Pi^0(\theta)$, where $\Pi^0(\theta)$ is the prior. Ultimately, we are interested in $\Pi_{1,0}(\theta; y)$, so we use CDA Gibbs as an efficient proposal for Metropolis-Hastings. That is, we propose θ^* from $Q(\theta; \cdot)$ where

$$Q_{r,b}(\theta; A) = \int_{(\theta^*, z) \in A \times \mathcal{Z}} \pi_{r,b}(z; \theta, y) f_{r,b}(\theta^*; z, y) dz d\theta^* \quad (3)$$

for $A \subseteq \Theta$, where $\pi_{r,b}$ and $f_{r,b}$ denote the conditional densities of z and θ in the Gibbs sampler with invariant measure $\Pi_{r,b}$. By tuning working parameters during an adaptation phase to minimize the lag-1 autocorrelation for the identity function while maximizing the Metropolis-Hastings acceptance rate, we can select values of the working parameters that yield a computationally efficient algorithm.

2.1 Initial example: Probit with improper prior

We introduce our calibration approach through a binomial probit model example:

$$y_i \sim \text{Bernoulli}(p_i), \quad p_i = \Phi(x_i \theta),$$

with improper prior $\pi(\theta) \propto 1$. The basic data augmentation algorithm (Tanner and Wong, 1987; Albert and Chib, 1993) has the update rule

$$z_i \mid \theta, x_i, y_i \sim \begin{cases} \text{No}_{[0, \infty)}(x_i \theta, 1) & \text{if } y_i = 1 \\ \text{No}_{(-\infty, 0]}(x_i \theta, 1) & \text{if } y_i = 0 \end{cases}$$

$$\theta \mid z, x, y \sim \text{No}((X'X)^{-1}X'z, (X'X)^{-1}),$$

where $\text{No}_{[a, b]}(\mu, \sigma^2)$ is the normal distribution with mean μ and variance σ^2 truncated to the interval $[a, b]$.

We propose to make the Gibbs step sizes tunable by introducing an auxiliary parameter r_i multiplying the variance of z_i , while also reducing the bias caused by r_i through adjusting the mean by another auxiliary parameter b_i . I don't find it particularly clear why this reduces the bias at this point in the paper. We might want to make a more explicit comment on why it helps. These adjustments yield

$$\text{pr}(y_i = 1 \mid \theta, x_i, r_i, b_i) = \int_0^\infty \frac{1}{\sqrt{2\pi r_i}} \exp\left(-\frac{(z_i - x_i \theta - b_i)^2}{2r_i}\right) dz_i = \Phi\left(\frac{x_i \theta + b_i}{\sqrt{r_i}}\right), \quad (4)$$

leading to the modified data augmentation algorithm

$$z_i \mid \theta, x_i, y_i \sim \begin{cases} \text{No}_{[0, \infty)}(x_i \theta + b_i, r_i) & \text{if } y_i = 1 \\ \text{No}_{(-\infty, 0]}(x_i \theta + b_i, r_i) & \text{if } y_i = 0 \end{cases} \quad (5)$$

$$\theta \mid z, X \sim \text{No}((X'R^{-1}X)^{-1}X'R^{-1}(z - b), (X'R^{-1}X)^{-1}),$$

where $R = \text{diag}(r_1, \dots, r_n)$, $b = (b_1, \dots, b_n)'$. This differs fundamentally from the parameter expansion algorithms of Liu and Wu (1999) and Meng and Van Dyk (1999) that rescale θ by $r^{-1/2}$, which does not impact the conditional variance of θ and so does not affect the numerator of (2). For fixed $r = (r_1, \dots, r_n)$ and $b = (b_1, \dots, b_n)$, (4) defines a proper Bernoulli likelihood for y_i conditional on parameters, and therefore the transition kernel $K_{r,b}((\theta, z); \cdot)$ defined by the Gibbs update rule in (5) has a unique invariant measure for fixed r, b , which we denote $\pi_{r,b}(\theta, z \mid y)$. We refer to the Gibbs sampler obtained for any fixed r, b as CDA Gibbs.

To preserve the original target $\pi_{1,0}(\theta, z \mid y)$, we use (5) to generate an M-H proposal. Specifically, we propose from $Q(\theta^*; \theta) = \int f(\theta^*; z, y) \pi(z; \theta, y) dz$, the θ -marginal of the transition kernel $K_{r,b}((\theta^*, z^*); (\theta, z))$. Because Gibbs marginals are reversible, the acceptance probability is given by

$$1 \wedge \frac{Q(\theta; \theta^*) \pi(\theta^*) \prod_i L(x_i \theta^*; y_i)}{Q(\theta^*; \theta) \pi(\theta) \prod_i L(x_i \theta; y_i)} = 1 \wedge \frac{\prod_i L_{r,b}(x_i \theta; y_i) L(x_i \theta^*; y_i)}{\prod_i L_{r,b}(x_i \theta^*; y_i) L(x_i \theta; y_i)}, \quad (6)$$

where $L_{r,b}(\eta_i; y_i) = \Phi(\frac{\eta_i + b_i}{\sqrt{r_i}})^{y_i} (1 - \Phi(\frac{\eta_i + b_i}{\sqrt{r_i}}))^{(1-y_i)}$ and we denote $L_{1,0}$ by L . Setting $r_i = 1$ and $b_i = 0$ leads to acceptance rate of 1, which corresponds to the original Gibbs sampler.

For insight into the relationship between r and step size, consider the θ -marginal autocovariance in the CDA Gibbs sampler evolving according to $K_{r,b}$:

$$\begin{aligned} \text{cov}_{r,b}(\theta_t \mid \theta_{t-1}, X, z, y) &= (X'R^{-1}X)^{-1} + (X'R^{-1}X)^{-1}X'R^{-1}\text{cov}(z - b|R)R^{-1}X(X'R^{-1}X)^{-1} \\ &\geq (X'R^{-1}X)^{-1}, \end{aligned} \tag{7}$$

In the special case where $r_i = r_0$ for all i , we have

$$\text{cov}_{r,b}(\theta_t \mid \theta_{t-1}, X, z, y) \geq r_0(X'X)^{-1},$$

so that all of the conditional variances are increased by at least a factor of r_0 . This holds uniformly over the entire state space, so it follows that

$$\mathbb{E}_{\pi_{r,b}}[\text{var}(\theta_j \mid z)] \geq r_0 \mathbb{E}_{\pi}[\text{var}(\theta_j \mid z)].$$

Of course, this auxiliary Gibbs chain is used to generate proposals, so the key to calibrated data augmentation (CDA) is to choose r, b to make $\mathbb{E}_{\pi_{r,b}}[\text{var}(\theta_j \mid z)]$ close to $\text{var}_{\pi_{r,b}}(\theta_j \mid z)$, while additionally maximizing the M-H acceptance probability. Although not obvious, it is in general possible to make the conditional and marginal variances of the Gibbs sampler at stationarity nearly equal, even though r, b affect both. Later, we argue that choosing r, b in this way is similar to minimizing the KL divergence between $\pi_{r,b}(\theta|y)$ and $\pi(\theta|y)$. Before describing a general algorithm to choose r, b , we illustrate how CDA can be used to address the problem with DA studied in Johndrow et al. (2016).

2.2 Imbalanced data intercept only case

In an intercept-only model, the variance is bounded by $(\sum_i r_i^{-1})^{-1}$ via (7), which is $1/n$ times the harmonic mean of the r_i s. Johndrow et al. (2016) show that when $\sum_i y_i = 1$ and $r_i = 1$, $\text{var}(\theta_t \mid \theta_{t-1})$ is approximately $n^{-1} \log n$, while the width of the high probability region of the posterior is order $(\log n)^{-1}$, leading to slow mixing. To achieve step sizes consistent with the width of the high posterior probability region, we need

$$\left(\sum_i r_i^{-1} \right)^{-1} \approx (\log n)^{-1},$$

so if $r_i = r$ for all i , $r \approx n / \log n$.

To illustrate CDA, consider an intercept only probit model, with $\sum_i y_i = 1$ and $n = 10^4$. Letting $r = n / \log n$, we then choose the b_i 's to increase the acceptance rate in the M-H step. In this simple example, it is easy to compute a “good” value of b_i , since $b_i = -3.7(\sqrt{r} - 1)$ results in $\text{pr}(y_i = 1) = \Phi(-3.7) = n^{-1} \sum_i y_i \approx 10^{-4}$ in the proposal distribution.

We run CDA Gibbs for these data and different values of r ranging from $r = 1$ to $r = 5,000$, with $r = 1,000 \approx n/\log n$ corresponding to the theoretically optimal value. Figure 1a plots autocorrelation functions (ACFs) for these different samplers without M-H adjustment. Autocorrelation is very high even at lag 40 for $r = 1$, while increasing r leads to dramatic improvements in mixing. There are no further gains in increasing r from the theoretically optimal value of $r = 1,000$ to $r = 5,000$. Figure 1b shows kernel-smoothed density estimates of the posterior of θ without M-H adjustment for different values of r and based on long chains to minimize the impact of Monte Carlo error; the posteriors are all centered on the same values but with variance increasing somewhat with r . With M-H adjustment such differences are removed; the M-H step has acceptance probability close to one for $r = 10, 100$, is 0.6 for $r = 1,000$, and 0.2 for $r = 5,000$.

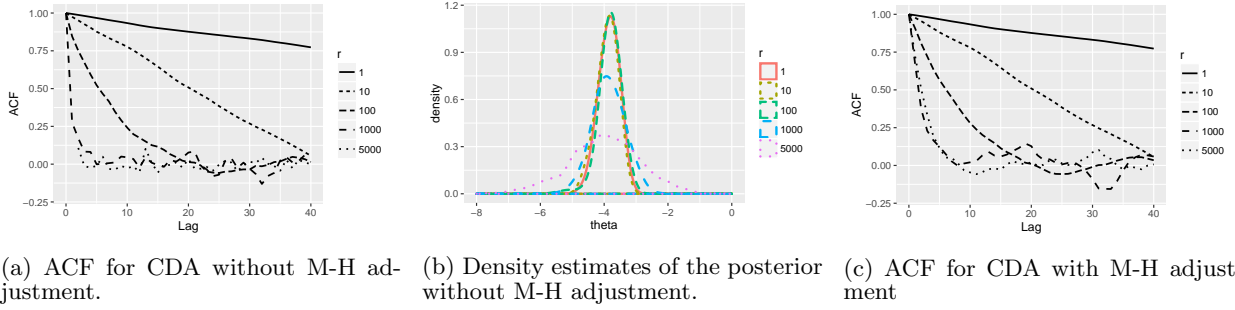

Figure 1: Autocorrelation functions (ACFs) and kernel-smoothed density estimates for different CDA samplers in intercept-only probit model.

2.3 Choice of calibration parameters

As illustrated in the previous subsection, efficiency of CDA is dependent on a good choice of the calibration parameters $r = (r_1, \dots, r_n)$ and $b = (b_1, \dots, b_n)$. In the intercept-only case for probit, it was possible to analytically calculate appropriate values of these parameters, but in general an empirical approach is needed. We now propose a simple and efficient algorithm for calculating these parameters relying on Fisher information. In large samples, the Fisher information evaluated at the posterior mode is a good approximation to the posterior covariance. Thus, if we knew the posterior mode under $L_{r,b}$, choosing r, b to minimize

$$\begin{aligned} \Delta_{\mathcal{I}}(\hat{\theta}_{MAP}, \hat{z}_{MAP}) &= \|\mathcal{I}_{r,b}(\hat{\theta}_{MAP}) - \mathcal{I}_{r,b}(\hat{\theta}_{MAP} | \hat{z}_{MAP})\|_F, \\ &= \left\| \mathbb{E} \left[\left(\frac{\partial}{\partial \theta} \log L_{r,b}(y; \theta) \right)^2 \middle| \hat{\theta}_{MAP} \right] - \mathbb{E} \left[\left(\frac{\partial}{\partial \theta} \log f_{r,b}(y; \theta, z) \right)^2 \middle| \hat{\theta}_{MAP}, \hat{z}_{MAP} \right] \right\|_F \end{aligned}$$

where $\|A\|_F$ is the Frobenius norm of A , would approximate values of r, b that result in fast mixing.

In general, we do not have access to the posterior mode, so we instead use samples from the Markov chain during an adaptation phase to dynamically update r_t, b_t . Specifically, we choose r_{t+1} to minimize $\Delta_{\mathcal{I}}(\theta_t, z_t)$, and set b_{t+1} to minimize $|L_{1,0}(\theta_t; y) - L_{r_{t+1}, b_{t+1}}(\theta_t; y)|$. Thus, we use r to reduce autocorrelation

in the neighborhood of (θ_t, z_t) , and b to make $L_{r,b}$ close to $L_{1,0}$ in the neighborhood of θ_t . Intuitively, this will make the target distribution closer to the invariant measure of CDA Gibbs, and correspondingly increase the MH acceptance rate. For a concrete illustration, we describe the updating of r, b in the probit case. Putting $\eta_i = x_i \theta$, the Fisher information based on the marginal and the conditional posteriors are:

$$\mathcal{I}_{r,b}(\theta) = X' \text{diag} \left\{ \frac{\phi(\eta_i)^2}{\Phi(\eta_i)(1 - \Phi(\eta_i))} \right\} X, \quad \mathcal{I}_{r,b}(\theta | z) = X' R^{-1} X$$

respectively, where ϕ is the standard normal density. Therefore, setting $r_i = \frac{\Phi(\eta_i)(1 - \Phi(\eta_i))}{\phi(\eta_i)^2}$ makes $\Delta_{\mathcal{I}}(\theta_t, z_t) = 0$. The r_i 's can be calculated using this expression at low cost without calculating the full information matrix. We then choose b_t to increase the acceptance rate in the M-H step, $1 \wedge \prod_i \frac{L_{r,b}(\eta_i; y_i) L(\eta_i^*; y_i)}{L_{r,b}(\eta_i^*; y_i) L(\eta_i; y_i)}$. As η_i^* is unknown before proposed, we set $b_i = \eta_i(\sqrt{r_i} - 1)$ to ensure that $L_{r,b}(\eta_i; y_i) = L(\eta_i; y_i)$ and proposals near η_i have relatively large acceptance rate.

The proposal kernel we describe above is *adaptive*; that is, we have a collection of proposal kernels $\mathcal{Q} = \{Q_{r,b}\}_{(r,b) \in \mathbb{R}_+ \times \mathbb{R}}$, and we choose a different member of \mathcal{Q} at each iteration to create the proposal. The *target* for the resulting transition kernel is $\Pi_{1,0}$ for every $Q_{r,b}$ because of the Metropolis-Hastings rejection step. In general, ergodicity of adaptive algorithms requires a diminishing adaptation condition; a general condition of this sort is given in (CITE Roberts 2007). Although the algorithm we describe is unlikely to satisfy diminishing adaptation if updating of r, b continues indefinitely, the condition is trivially satisfied by any algorithm that stops adaptation after a fixed number of iterations. Thus, for simplicity, we choose a tuning period length, after which we fix r, b at their current values. More sophisticated adaptation schemes could be devised; however, the fixed tuning period works well empirically.

To illustrate, we consider a probit regression with an intercept and two predictors $x_{i,1}, x_{i,2} \sim \text{No}(1, 1)$, with $\theta = (-5, 1, -1)'$, generating $\sum y_i = 20$ among $n = 10,000$. The Albert and Chib (1993) DA algorithm mixes slowly (Figure 2a and 2b). We also show the results of the parameter expansion algorithm (PX-DA) proposed by Liu and Wu (1999). PX-DA only mildly reduces the correlation, as it does not solve the variance mismatch problem. In contrast, applying CDA after a tuning period of 100 iterations, we obtain dramatically better mixing.

(a) Traceplot for the original DA, parameter expanded DA and CDA algorithms.

(b) ACF for original DA, parameter expanded DA and CDA algorithms.

Figure 2: Panel (a) demonstrates in traceplot and panel (b) in autocorrelation the substantial improvement in CDA by correcting the variance mis-match in probit regression with rare event data, compared with the original (Albert and Chib, 1993) and parameter-expanded methods (Liu and Wu, 1999).

2.4 Logistic regression example: A second calibration approach

Calibration was easy to achieve in the probit examples, because $\text{var}(\theta|z, y)$ does not involve the latent variable z . In cases in which the latent variable impacts the variance of the conditional posterior distribution of θ , we propose a different calibration strategy based on inflating the variance of $\pi(z|y)$ targeted towards increasing $\mathbb{E}_z \text{var}(\theta|z, y)$. In developing this second calibration strategy, we focus on the logistic regression model with

$$y_i \sim \text{Bernoulli}(p_i), \quad p_i = \frac{\exp(x_i \theta)}{1 + \exp(x_i \theta)},$$

and improper prior $\pi(\theta) = 1$. For this model, Polson et al. (2013) proposed Polya-Gamma data augmentation:

$$z_i \sim \text{PG}(1, |x_i \theta|),$$

$$\theta \sim \text{No}((X'ZX)^{-1}X'(y - 0.5), (X'ZX)^{-1}),$$

where $Z = \text{diag}(z_1, \dots, z_n)$. This algorithm relies on expressing the logistic regression likelihood as

$$L(y_i | x_i \theta) = \int \exp\{x_i \theta (y_i - 1/2)\} \exp\left\{-\frac{z_i (x_i \theta)^2}{2}\right\} \text{PG}(z_i | 1, 0) dz_i,$$

where $\text{PG}(a_1, a_2)$ denote the Polya-Gamma distribution with parameters a_1, a_2 , with $\mathbb{E}z_i = \frac{a_1}{2a_2} \tanh(\frac{a_2}{2})$.

Our previous calibration approach would have relied on inflating the variance in the conditional update of θ , but this unfortunately no longer works well due to the occurrence of Z in the conditional covariance. Instead, we rely on replacing $\text{PG}(z_i | 1, 0)$ with $\text{PG}(z_i | r_i, 0)$ in the step for updating the latent data. Smaller r_i can lead to larger $\mathbb{E}_z \text{var}(\theta|z, y)$, providing a route towards calibration. Applying the bias-adjustment term b_i to the linear predictor $\eta_i = x_i \theta$ leads to

$$L_r(x_i \theta; y_i) = \int_0^\infty \exp\{(x_i \theta + b_i)(y_i - r_i/2)\} \exp\left\{-\frac{z_i (x_i \theta + b_i)^2}{2}\right\} \text{PG}(z_i | r_i, 0) dz_i$$

$$= \frac{\exp\{(x_i\theta + b_i)y_i\}}{\{1 + \exp(x_i\theta + b_i)\}^{r_i}}, \quad (8)$$

and the update rule for the proposal:

$$z_i \sim \text{PG}(r_i, |x_i\theta + b_i|),$$

$$\theta^* \sim \text{No}\left((X'ZX)^{-1}X'(y - r/2 - Zb), (X'ZX)^{-1}\right),$$

with acceptance probability:

$$1 \wedge \frac{\prod_i L_r(x_i\theta; y_i)L(x_i\theta^*; y_i)}{\prod_i L_r(x_i\theta^*; y_i)L(x_i\theta; y_i)} = 1 \wedge \prod_i \frac{\{1 + \exp(x_i\theta)\}\{1 + \exp(x_i\theta^* + b_i)\}^{r_i}}{\{1 + \exp(x_i\theta^*)\}\{1 + \exp(x_i\theta + b_i)\}^{r_i}},$$

where $L(\theta; y_i) = \frac{\exp(\theta y_i)}{1 + \exp(\theta)}$.

To demonstrate why smaller r_i leads to larger $\mathbb{E}_z(X'ZX)^{-1}$, we compute the first negative moment of the Polya-Gamma distribution. Combining Cressie et al. (1981) and Polson et al. (2013), $\mathbb{E}z_i^{-1} = \int_0^\infty \prod_{k=1}^\infty (1 + d_k^{-1}t)^{-r_i} dt$ with $d_k = 2(k - \frac{1}{2})^2\pi^2 + \frac{(x_i\theta + b_i)^2}{2}$.

For choosing r during tuning, we compare the two Fisher information matrices based on the marginal and conditional; for the latter, we marginalize out z_i by taking the expectation:

$$X' \text{diag} \left\{ \frac{\exp(x_i\theta)}{\{1 + \exp(x_i\theta)\}^2} \right\} X, \quad X' \text{diag} \left\{ \frac{r_i}{2|x_i\theta + b_i|} \tanh\left(\frac{|x_i\theta + b_i|}{2}\right) \right\} X$$

To correct the difference, we choose r_i to be $\frac{\exp(x_i\theta)}{\{1 + \exp(x_i\theta)\}^2} 2|x_i\theta + b_i| / \tanh(\frac{|x_i\theta + b_i|}{2})$. To optimize the acceptance rate, given the value of r_i and $x_i\theta$, setting $\{1 + \exp(x_i\theta)\} = \{1 + \exp(x_i\theta + b_i)\}^{r_i}$ yields $b_i = \log[\{1 + \exp(x_i\theta)\}^{1/r_i} - 1] - x_i\theta$.

As a numerical illustration, we use a two parameter intercept-slope model with $x_1 \sim \text{No}(0, 1)$ and $\theta = (-9, 1)'$. With $n = 10^5$, we obtain rare outcome data with $\sum y_i = 50$. We ran the original DA algorithm (Polson et al., 2013) and an independence chain M-H sampler using a multivariate normal proposal $\theta^*|\theta \sim \text{No}(\theta^*|\theta, \mathcal{I}^{-1}(\theta))$, with $\mathcal{I}(\theta)$ the Fisher information matrix based on the marginal posterior. For CDA we tuned r and b for 100 steps, reaching an acceptance rate of 0.8, and then stopped adaptation and ran an additional burn-in of 100 iterations, with the following 500 samples collected. Shown in Figure 3, both DA and M-H with a normal proposal mix slowly, exhibiting strong autocorrelation even lag 40, while CDA has dramatically better mixing.

(a) Traceplots for DA, CDA and M-H with multivariate normal proposal. (b) ACF for DA, CDA and M-H with multivariate normal proposal.

Figure 3: Panel (a) demonstrates in traceplot and panel (b) in autocorrelation the substantial improvement of CDA in logistic regression with rare event data, compared with the original DA (Polson et al., 2013) and the M-H algorithm with multivariate normal proposal (MH-MVN).

The section that was previously here seemed mostly duplicative of my edits to earlier parts, so I commented it out

3 Theory: ergodicity and tuning

In this section, we provide basic theoretical support for CDA algorithms. First, we show that CDA M-H is ergodic. This is basically a consequence of CDA Gibbs being ergodic for fixed r, b and the fact that $\Pi_{r,b}$ and Π are absolutely continuous with respect to Lebesgue measure on \mathbb{R}^p .

Remark 1 (ergodicity). *Assume that $\Pi(d\theta)$ and $\Pi_{r,b}(d\theta)$ have densities with respect to Lebesgue measure on \mathbb{R}^p , and that $K_{r,b}((\theta, z); (\theta', z')) > 0 \forall ((\theta, z), (\theta', z')) \in (\Theta \times \mathcal{Z}) \times (\Theta \times \mathcal{Z})$. Then, for fixed r, b , CDA Gibbs is ergodic with invariant measure $\Pi_{r,b}(d\theta, dz)$. Moreover, a Metropolis-Hastings algorithm with proposal kernel $Q_{r,b}(\theta'; \theta)$ as defined in (3) with fixed r, b is ergodic with invariant measure $\Pi(d\theta)$.*

Proof. For any r, b , the conditionals $\Pi_{r,b}(z | \theta)$ and $\Pi_{r,b}(\theta | z)$ are well-defined for all $z \in \mathcal{Z}, \theta \in \Theta$, and therefore the Gibbs transition kernel $K_{r,b}((\theta, z); \cdot)$ and corresponding marginal kernels $Q_{r,b}(\theta; \cdot)$ are well-defined. Moreover, for any $(z, \theta) \in \mathcal{Z} \times \Theta$, we have $\mathbb{P}[(\theta', z') \in A | (\theta, z)] > 0$ by assumption. Thus $K_{r,b}$ is aperiodic and $\Pi_{r,b}$ -irreducible.

$Q_{r,b}(\theta'; \theta)$ is aperiodic and $\Pi_{r,b}(\theta)$ -irreducible, since it is the θ marginal transition kernel induced by $K_{r,b}((\theta, z); \cdot)$. Thus, it is also $\Pi(\theta)$ -irreducible so long as $\Pi \gg \Pi_{r,b}$, where for two measures μ, ν , $\mu \gg \nu$ indicates absolute continuity. Since $\Pi, \Pi_{r,b}$ have densities with respect to Lebesgue measure, $\Pi_{r,b}$ -irreducibility implies Π irreducibility. Moreover, $Q(\theta; \theta') > 0$ for all $\theta \in \Theta$. Thus, by Theorem 3 of [CITE Roberts 1994], CDA M-H is Π -irreducible and aperiodic. \square

Having established ergodicity of both CDA Gibbs and CDA M-H under weak assumptions that hold for all of the data augmentation strategies we consider here, we now provide a semi-rigorous argument for why our approach to tuning r and b results in both rapid convergence and closeness of $\Pi_{r,b}$ to Π . Suppose there exists r such that

$$\mathbb{E}_{\Pi_{r,b}}[\text{var}(\theta \mid z)] = \text{var}_{\Pi_{r,b}}(\theta)$$

for any value of b . This is a simplification, since our adaptation strategies only allow us to control the discrepancy between the Fisher information at the current state. By tuning r during the adaptation phase to make the lag-1 autocorrelation for the identity function small, we can numerically approximate the correct value of r .

This is obviously much weaker than minimizing the autocorrelation for worst-case functions. However, for the sake of exposition, we will proceed on the assumption that (1) we can make the lag-1 autocorrelation for the identity function zero by appropriately tuning r and (2) this is sufficient to obtain a Gibbs transition kernel that generates nearly *independent* samples. This makes the rationale for tuning b to increase the Metropolis acceptance probability much clearer. First, we note the form of the Metropolis acceptance ratios, which we have used previously without rigorous justification.

Remark 2. *The CDA M-H acceptance ratio is given by*

$$\frac{L(\theta'; y)\Pi^0(\theta')Q_{r,b}(\theta; \theta')}{L(\theta; y)\Pi^0(\theta)Q_{r,b}(\theta'; \theta)} = \frac{L(\theta'; y)L_{r,b}(\theta; y)}{L(\theta; y)L_{r,b}(\theta'; y)} \quad (9)$$

Proof. Since $Q_{r,b}(\theta; \theta')$ is the θ marginal of a Gibbs transition kernel, and Gibbs is reversible on its margins, we have

$$Q(\theta; \theta')\Pi_{r,b}(\theta) = Q(\theta'; \theta)\Pi_{r,b}(\theta'),$$

and so

$$\begin{aligned} \frac{L(\theta'; y)\Pi^0(\theta')Q(\theta; \theta')}{L(\theta; y)\Pi^0(\theta)Q(\theta'; \theta)} &= \frac{L(\theta'; y)\Pi^0(\theta')L_{r,b}(\theta; y)\Pi^0(\theta)}{L(\theta; y)\Pi^0(\theta)L_{r,b}(\theta'; y)\Pi^0(\theta')} \\ &= \frac{L(\theta'; y)L_{r,b}(\theta; y)}{L(\theta; y)L_{r,b}(\theta'; y)}. \end{aligned}$$

□

The expression in (9) will be near 1 at stationarity if

$$\int \log \left(\frac{L(\theta'; y)L_{r,b}(\theta; y)}{L(\theta; y)L_{r,b}(\theta'; y)} \right) Q_{r,b}(\theta'; \theta)\Pi(d\theta) \approx 0.$$

Now, suppose that a Markov chain evolving according to $K_{r,b}$ is rapidly mixing, so that for starting measures satisfying a condition like

$$\sup_A \frac{\nu(A)}{\Pi_{r,b}(A)} < M$$

for M not too large we have

$$\text{KL} \left(\Pi_{r,b} \parallel \int Q_{r,b}(\theta'; \theta) \nu(d\theta) \right) \quad \text{small.}$$

Then the symmetric KL is

$$\begin{aligned} \text{KL}(\Pi_{r,b} \parallel \Pi) + \text{KL}(\Pi \parallel \Pi_{r,b}) &= \int \Pi_{r,b}(d\theta) \log \frac{\Pi_{r,b}(\theta)}{\Pi(\theta)} + \int \Pi(d\theta) \log \frac{\Pi(\theta)}{\Pi_{r,b}(\theta)} \\ &= \int \Pi_{r,b}(d\theta) \log \frac{c_{r,b} L_{r,b}(\theta) \Pi_0(\theta)}{c L(\theta) \Pi_0(\theta)} + \int \Pi(d\theta) \log \frac{c L(\theta) \Pi_0(\theta)}{c_{r,b} L_{r,b}(\theta) \Pi_0(\theta)} \\ &\approx \int K_{r,b}(\theta'; \theta) \Pi(d\theta) \log \frac{L_{r,b}(\theta')}{L(\theta')} + \int \Pi(d\theta) \log \frac{L(\theta)}{L_{r,b}(\theta)} \\ &= \mathbb{E} \left[\frac{L_{r,b}(\theta') L(\theta)}{L_{r,b}(\theta) L(\theta')} \right], \end{aligned}$$

for $\theta \sim \Pi$ and $\theta' \mid \theta \sim K_{r,b}(\theta'; \theta)$, so that tuning b to make the M-H acceptance ratio larger will tend to make the symmetric KL between $\Pi_{r,b}$ and Π small. This justifies the approach of using the acceptance ratio to tune b . As the acceptance ratio approaches 1, CDA M-H and CDA Gibbs coincide, and the CDA Gibbs invariant measure is identically Π , but the corresponding Gibbs sampler converges rapidly.

4 Co-Browsing Behavior Application

We apply CDA to an online browsing activity dataset. The dataset contains a two-way table of visit count by users who browsed one of 96 client websites of interests, and one of the $n = 59,792$ high-traffic sites during the same browsing session. We refer to visiting more than one site during the same session as co-browsing. For each of the client websites, it is of large commercial interests find out the high-traffic sites with relatively high co-browsing rates, so that ads can be more effectively placed. For the computational advertising company, it is also useful understand the the co-browsing behavior and predict traffic pattern of users. We consider two models for these data.

4.1 Hierarchical Binomial Model for Estimating Co-browsing Rates

We initially focus on one client website and analyze co-browsing rates with the high-traffic sites. With the total visit count N_i available for the i th high-traffic site, the count of co-browsing y_i can be considered as the result of a binomial trial. with y_i extremely small relative to N_i (with ratio (0.00011 ± 0.00093)), the maximum likelihood estimate y_i/N_i can have poor performance. For example, when $y_i = 0$, estimating the rate as exactly 0 is not ideal. Therefore, it is useful to consider a hierarchical model to allow borrowing of information across high-traffic sites.

$$y_i \sim \text{Binomial} \left(N_i, \frac{\exp(\theta_i)}{1 + \exp(\theta_i)} \right), \quad \theta_i \stackrel{iid}{\sim} \text{No}(\theta_0, \sigma_0^2), \quad i = 1 \dots n$$

$$(\theta_0, \sigma_0^2) \sim \pi(\theta_0, \sigma_0^2)$$

Based on expert opinion in quantitative advertising, we use a weakly informative prior $\theta_0 \sim \text{No}(-12, 49)$ and uniform prior on σ_0^2 . Similar to the logistic regression, we calibrate the binomial Polya-Gamma augmentation, leading to the proposal likelihood:

$$L_r(\theta_i : y_i, N_i, r_i, b_i) = \frac{\exp(\theta_i + b_i)_i^y}{\{1 + \exp(\theta_i + b_i)\}^{N_i r_i}}$$

Conditioned on the latent Polya-Gamma latent variable z_i , each proposal θ_i^* can be sampled from:

$$z_i \sim \text{PG}((N_i r_i), \theta_i + b_i)$$

$$\theta_i^* \sim \text{No} \left(\frac{y_i - r_i N_i / 2 - z_i b_i + \theta_0 / \sigma_0^2}{z_i + 1 / \sigma_0^2}, \frac{1}{z_i + 1 / \sigma_0^2} \right),$$

and accepted or rejected using an M-H step. Similar to logistic regression, the auxiliary parameters are chosen as $r_i = \frac{\exp(\theta_i)}{\{1 + \exp(\theta_i)\}^2} / \left(\frac{1}{2|\theta_i + b_i|} \tanh \frac{|\theta_i + b_i|}{2} \right)$ and $b_i = \log[\{1 + \exp(\theta_i)\}^{1/r_i} - 1] - \theta_i$ during adaptation. Since θ_i 's are conditionally independent, the calibrated proposal can be individually accepted with high probability for each i . This leads to a high average acceptance of 0.9, despite the high dimensionality of 59,792 θ_i 's.

Figure 4 shows the boxplots of the ACFs for all θ_i 's. We compare the result with the original DA (Polson et al., 2013). We run DA for 100,000 steps and CDA for 2,000 steps, so that they have approximately the same effective sample size. All of the parameters mix poorly in DA; CDA leads to significant improvement with autocorrelation rapidly decaying to close to zero within 5 lags. Table 1 lists the posterior mean and credible intervals for the parameters, as well as the effective sample size (T_{eff}) per iteration, calculated with the CODA package in R.

To provide a reference, we ran Hamiltonian Monte Carlo (HMC) provided by the STAN software (Carpenter et al., 2016). HMC enjoys very good mixing performance but is computationally intensive due to the numeric leapfrog steps. The parameter estimates from CDA and HMC are remarkably close, while critically slow mixing in the original DA caused poor estimates.

(a) ACFs of the rate parameters θ_i using DA. (b) ACFs of the rate parameters θ_i using CDA. (c) ACFs of the rate parameters θ_i using HMC.

Figure 4: Boxplots of the ACFs show the mixing of the 59,792 parameters in the hierarchical binomial model, for the original DA (Polson et al., 2013), CDA and HMC.

	DA	CDA	HMC
$\sum \theta_i / n$	-10.03 (-10.16, -9.87)	-12.05 (-12.09, -12.02)	-12.06 (-12.09, -12.01)
$\sum \theta_i^2 / n$	102.25 (98.92, 105.23)	153.04 (152.06, 154.05)	153.17 (152.02, 154.29)
θ_0	-10.03 (-10.17, -9.87)	-12.05 (-12.09, -12.01)	-12.06 (-12.10, -12.01)
σ^2	1.60 (1.36, 1.82)	7.70 (7.49, 7.88)	7.71 (7.51, 7.91)
T_{eff}/T	0.0085 (0.0013, 0.0188)	0.5013 (0.1101, 1.0084)	0.8404 (0.5149, 1.2470)
Avg Computing Time / T	1.2 sec	1.2 sec	6 sec
Avg Computing Time / T_{eff}	140.4 sec	0.48 sec	1.3 sec

Table 1: Parameter estimates (with 95% credible intervals) and effective sample sizes (T_{eff}) of the DA, CDA and HMC in hierarchical binomial model. CDA provides parameter estimates as accurate as HMC, and is more computationally efficient than HMC.

4.2 Poisson Log-Normal Model for Web Traffic Prediction

The co-browsing on one high-traffic site and one client site is commonly related to the click-through of user from the former to the latter. Therefore, the count of the co-browsing is a useful indication of the click-through traffic. For any given client website, being able to predict the high traffic sites that could generate most traffic is certainly of high values. Therefore, we consider a Poisson regression model. We choose the co-browsing count of one client website as the outcome y_i , and the count of other 95 websites as the predictor x_{ij}^* for $i = 1 \dots 59,792$ and $j = 1 \dots 95$. To use them as predictors in Poisson log-normal model, we transform the count onto the log scale with $x_{ij} = \log(x_{ij}^* + 1)$. To allow over-dispersion, we use a random intercept for each i .

$$y_i \sim \text{Poisson}(\exp(x_i \beta + \tau_i)), \quad \tau_i \stackrel{iid}{\sim} \text{No}(\tau_0, \nu^2), \quad i = 1 \dots n$$

$$\beta \sim \text{No}(0, I\sigma_\beta^2), \quad \tau_0 \sim \text{No}(0, \sigma_\tau^2) \quad \nu^2 \sim \pi(\nu^2).$$

We assign a weakly informative prior for β and τ_0 with $\sigma_\beta^2 = \sigma_\tau^2 = 100$. For the over-dispersion parameter ν^2 , we assign a non-informative uniform prior.

To focus on data augmentation, we first rule out other factors that can potentially contribute to slow mixing. In this case, random effects τ_i can be problematic for β when they are sampled separately. Therefore,

we consider sampling β and τ jointly. Using $\tilde{X} = [I_n || X]$ for the $n \times (n + p)$ juxtaposed projection matrix, and $\eta_i = x_i\beta + \tau_i$ for the linear predictor, the model can be viewed as a linear predictor with $n + p$ coefficients, for which the parameters $\theta = \{\tau, \beta\}'$ can be sampled jointly in a block.

The data augmentation for Poisson log-normal model is less known. Zhou et al. (2012) proposed to utilize $\text{Poisson}(\eta_i)$ as the limit of the negative binomial $\text{NB}(\lambda, \frac{\eta_i}{\lambda + \eta_i})$ with $\lambda \rightarrow \infty$, and used moderate $\lambda = 1,000$ for approximation. The method can be simplified as the following:

$$L(x_i\beta, \tau_i; y) = \frac{1}{y!} \frac{\exp(y_i\eta_i)}{\exp\{\exp(\eta_i)\}} = \frac{1}{y!} \lim_{\lambda \rightarrow \infty} \frac{\exp(y_i\eta_i)}{\{1 + \exp(\eta_i)/\lambda\}^\lambda}. \quad (10)$$

With finite λ approximation, it has a Polya-Gamma augmented sampling. Using Gibbs sampler, the approximate posterior can be obtained via:

$$\begin{aligned} z_i &\sim \text{PG}(\lambda, \eta_i - \log \lambda) \\ \theta &\sim \text{No}((\tilde{X}'Z\tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma_\beta^2 \cdot I_p \end{bmatrix})^{-1} \{ \tilde{X}'(y - \lambda/2 + Z \log \lambda) + \begin{bmatrix} \tau_0/\sigma_\tau^2 1_n \\ 0_p \end{bmatrix} \}, \\ &\quad (\tilde{X}'Z\tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma_\beta^2 \cdot I_p \end{bmatrix})^{-1}). \end{aligned}$$

However, this approximate based data augmentation is inherently problematic. For finite λ approximation, setting 1,000 would cause large approximation error. As in (10), the approximating denominator has $(1 + \exp(\eta_i)/\lambda)^\lambda = \exp\{\exp(\eta_i) + \mathcal{O}(\exp(2\eta_i)/\lambda)\}$; for moderately large $\eta_i \approx 10$, λ needs to be at least 10^9 to make $\exp(2\eta_i)/\lambda$ close to 0. This large error cannot be corrected with an additional M-H step, since the acceptance rate would be too low. On the other hand, it is not practical to use a large λ in a Gibbs sampler, since it would otherwise create extremely large z_i and small conditional covariance for θ .

This is where calibration can solve this dilemma. We first choose a very large λ (10^9) to control the approximation error, then use a small fractional r_i multiplying to λ for calibration. This leads to a proposal likelihood similar to the logistic CDA:

$$L_r(x_i\theta; y_i) = \frac{\exp(\eta_i - \log \lambda + b_i)^{y_i}}{\{1 + \exp(\eta_i - \log \lambda + b_i)\}^{r_i\lambda}},$$

and proposal update rule:

$$\begin{aligned} z_i &\sim \text{PG}(r_i\lambda, \eta_i - \log \lambda + b_i) \\ \theta^* &\sim \text{No}((\tilde{X}'Z\tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma_\beta^2 \cdot I_p \end{bmatrix})^{-1} \{ \tilde{X}'(y - r\lambda/2 + Z \log(\lambda - b)) + \begin{bmatrix} \tau_0/\sigma_\tau^2 1_n \\ 0_p \end{bmatrix} \}, \\ &\quad (\tilde{X}'Z\tilde{X} + \begin{bmatrix} 1/\nu^2 \cdot I_n & 0 \\ 0 & 1/\sigma_\beta^2 \cdot I_p \end{bmatrix})^{-1}). \end{aligned}$$

Let $\eta_i^* = \tilde{X}\theta^*$, the proposal is accepted with probability (based on Poisson density and the approximation $L_r(x_i\theta; y_i)$):

$$1 \wedge \prod_i \frac{\exp\{\exp(\eta_i)\}}{\exp\{\exp(\eta_i^*)\}} \frac{\{1 + \exp(\eta_i^* - \log \lambda + b_i)\}^{r_i \lambda}}{\{1 + \exp(\eta_i - \log \lambda + b_i)\}^{r_i \lambda}}.$$

During the adaptation, we set $r_i = 1/c_0 \tau_i \exp(\eta_i) / \left(\frac{\lambda}{2|\eta_i + b_i - \log \lambda|} \tanh \frac{|\eta_i + b_i - \log \lambda|}{2} \right)$ based on the Fisher information. We found the acceptance rate too low with $c_0 = 1$, which indicates an overestimation of mis-calibration. Therefore, we reduce c_0 and obtained an acceptance rate of 0.6. Conditionally on r_i , we used $b_i = \log[\exp\{\exp(\eta_i - \log \lambda - \log r_i)\} - 1] - \eta_i + \log \lambda$.

To compare, we ran approximate DA Gibbs sampler with $\lambda = 1,000$, CDA with M-H proposal and HMC. We ran approximate DA for 200,000 steps, CDA for 2,000 steps and HMC for 20,000 steps so that they have approximately the same effective sample size. For CDA, we used the first 1,000 steps for adapting r and b . Figure 5 shows the mixings of DA and CDA. Surprisingly, even with small λ , in approximate DA, all of the parameters still mix poorly; HMC seemed to be impacted by the random effects and most of parameters remain highly correlated within 40 lags; CDA substantially improves the mixing. Table 2 compares all three algorithms. CDA is clearly the best algorithm to generate the highest effective sample size within the same computing time.

Figure 5: CDA significantly improves the mixing of the parameters in the Poisson log-normal.

To evaluate the prediction performance, we use another dataset $\{y_{i,new}, x_{i,new}\}$ collected during a different time period for validation. We use the posterior mean $\{\hat{\tau}, \hat{\beta}\}$ for the prediction $\hat{y}_{i,new} = \exp(x_{i,new}\hat{\theta} + \hat{\tau}_i)$; cross-validation root-mean-squared error between $y_{i,new}$ and $\hat{y}_{i,new}$ is computed. CDA performs quite well and the validation error that is 4 times lower than DA.

5 Discussion

Data augmentation is a useful technique to sample posterior from the closed-form conditional. It has been discovered that it could severely slow down the mixing, caused by the gap between conditional variance given augmented data and marginal variance. With data size increases and become complex, it is common for the conditional distribution of the parameter to deviate from the area that has reasonable mixing performance. As we show in the previous examples, this quickly leads to an un-manageable increase in the computational time and poor performance in estimation.

To address this problem, we propose a general class of method to calibrate the conditional variance. With a new parameter to adjust the step size, the transition in each iteration is increased onto the same order of the marginal variance. The generated samples are used as proposal in the Metropolis-Hastings to obtain correct posterior. In this article, we demonstrate that this strategy is generally applicable when $\theta | z$ belongs to the location-scale family. We expect it to be extensible to any conditional distribution with a variance or scale.

We would like to draw some further comparison between CDA and HMC. Both algorithms rely on finding good proposal by searching an area far from the current state. The key difference lies in the computing efficiency. HMC is computationally intensive since Hamiltonian dynamics often requires multiple numeric steps, as it lacks closed-form solution in most of time. CDA adds a little extra cost to the original Gibbs sampler and needs only one step for generating proposal. Therefore, when the data augmentation exists, CDA is always much more efficient.

In this article, we insist on obtaining the exact posterior, to provide an analysis on the mixing property. Without the Metropolis-Hastings step, the sampling strategy in calibrated data augmentation can be used alone to generate approximate posterior.

6 Appendix

6.1 Proofs

6.1.1 Lemma 1

As the M-H step in CDA is equivalent to sampling from the mixture that:

$$(1 - p)\delta_{\theta'} + pf_{CDA}(\theta^*; z')$$

where p is the acceptance probability in (6) and f_{CDA} is the calibrated proposal distribution. Its conditional variance is:

$$\begin{aligned} \text{var}_{CDA}\{s(\theta)|z', \theta'\} &= (1 - p)s(\theta')^2 + p\mathbb{E}_{CDA}\{s(\theta^*)^2|z'\} - [(1 - p)s(\theta') + p\mathbb{E}_{CDA}\{s(\theta^*)|z'\}]^2 \\ &= (1 - p)[s(\theta')^2 - (1 - p)s(\theta')^2 - 2ps(\theta')\mathbb{E}_{CDA}\{s(\theta^*)|z'\} + p\mathbb{E}_f\{s(\theta^*)|z'\}^2] \\ &\quad + p[\mathbb{E}_{CDA}\{s(\theta^*)^2|z'\} - \mathbb{E}_{CDA}\{s(\theta^*)|z'\}^2] \end{aligned}$$

$$\begin{aligned}
&= (1-p)p[s(\theta') - \mathbb{E}_{CDA}\{s(\theta^*)|z'\}]^2 + p \cdot \text{var}_{CDA}(s(\theta^*)|z') \\
&\geq p \cdot \text{var}_{CDA}(s(\theta^*)|z') \\
&\geq p_0 \cdot \text{var}_{CDA}(s(\theta^*)|z')
\end{aligned}$$

6.1.2 Theorem 1

With Lemma 1,

$$\begin{aligned}
\mathbb{E}[\text{var}_{CDA}\{s(\theta)|z', \theta'\}] &\geq p_0 \cdot \mathbb{E}[\text{var}_{CDA}(s(\theta^*)|z')] \\
&\geq p_0 \gamma \cdot \mathbb{E}[\text{var}_{DA}(s(\theta^*)|z')].
\end{aligned}$$

Since the marginal variances are the same for two algorithms $\text{var}_{DA}\{s(\theta)\} = \text{var}_{CDA}\{s(\theta)\}$. When $p_0 \gamma \geq 1$, rearranging terms and taking supremum on both sides complete the proof.

6.2 Goodness-of-Fit and Cross-Validation for Poisson Regression

(a) Fitted vs true values using DA

(b) Fitted vs true values using CDA

(c) Prediction vs true values using DA

(d) Prediction vs true values using CDA

Figure 6: The posterior estimates produced by CDA is better fitted to the data and have more accurate prediction than DA.
